## Reliability-Constrained Area Optimization of VLSI Power/Ground Networks Via Sequence of Linear Programmings

Sheldon X.-D. Tan, C.-J. Richard Shi, and Jyh-Chwen Lee

**Abstract**—This paper presents a new method of sizing the widths of the power and ground routes in integrated circuits so that the chip area required by the routes is minimized subject to electromigration and *IR* voltage drop constraints. The basic idea is to transform the underlying constrained nonlinear programming problem into a sequence of linear programs. Theoretically, we show that the sequence of linear programs always converges to the optimum solution of the relaxed convex optimization problem. Experimental results demonstrate that the proposed sequence-of-linear-program method is orders of magnitude faster than the best-known method based on conjugate gradients with constantly better solution qualities.

**Index Terms**—Circuit modeling, linear programming, power distribution network, simulation and optimization.

### I. INTRODUCTION

Power/ground (P/G) networks connect the P/G supplies in the circuit modules to the P/G pads on a chip. An important problem in P/G network design is to use the minimum amount of chip area for wiring P/G networks, while avoiding potential reliability failures due to electromigration and excessive *IR* drops. Specifically, we are concerned with the problem of P/G-network optimization where the topologies of P/G networks are assumed to be fixed, and only the widths of wire segments are to be determined. Several methods have been developed to solve this problem [6]–[9]. However, to the best of our knowledge, none of

Manuscript received August 17, 2002; revised February 3, 2003. Some preliminary results of this paper were presented at the ACM/IEEE 38th Design Automation Conference, New Orleans, LA, June 1999. This paper was recommended by Associate Editor M. Sarrafzadeh.

these methods have been incorporated into commercial computer-aided design (CAD) tools and used by industry.

One major obstacle is that these methods are based on constrained nonlinear programming, a process known to be computationally intensive (NP-hard) [12]. These methods are applicable only to small size problems, while P/G networks in today's very large scale integration (VLSI) design may contain millions of wire segments (therefore, millions of variables). On the other hand, with the continuous shrinking of the chip feature size, P/G network optimization is becoming increasingly important, since more and more portions of the chip area are dedicated to P/G routings, and the problems of *IR* drop and electromigration deteriorate.

In this paper, we present a new method capable of solving the P/G optimization problem orders of magnitude faster than the best known method. Our method is inspired by a key observation made by Chowdhury that if currents in wire segments are fixed, and voltages are used as variables, then the resulting optimization problem is convex [8]. However, instead of using the conjugate gradient method as in [8], we show that the problem can be solved elegantly by a sequence of linear programs. We prove that there always exists a sequence of linear programs that converge to the optimal solution of the original convex optimization problem. Experimental results have demonstrated that usually a few linear programs are required to reach the optimal solution. The complexity of the proposed method is proportional to the complexity of linear programming (which can be solved in polynomial time [5], [12]). Therefore, our method is scalable, i.e., the CPU time increases approximately polynomially with the size of a network. In practice, we have observed that the new method is orders of magnitude faster than the conjugate gradient method with constantly better optimization results.

This paper is organized as follows. Section II reviews some previous work. Section III describes the formulation of the P/G network optimization problem. The new method is presented in Section IV. Some practical considerations are described in Section V. Experimental results from some large P/G networks are summarized in Section VI. Section VII concludes the paper.

### II. PREVIOUS WORK

It is generally assumed that the average current drawn by each module is known and is modeled as an independent current source (we do not consider the temporal correlations of current sources). The constraints from reliability and design rules include: 1) *IR* voltage drop constraints; 2) metal-migration constraints; 3) minimum width constraints; and 4) equal width constraints. The problem of determining the widths of wire segments of a P/G network to minimize the total P/G routing area subject to all these constraints is a constrained nonlinear optimization problem [6], [7].

In the method of Chowdhury and Breuer [6], resistance values and branch currents are selected as independent variables. Both the objective function and the *IR* voltage drop constraints become nonlinear. The augmented Lagrangian method combined with the steepest descent algorithm [1] is used to solve the resulting problem.

Dutta and Marek-Sadowska [9] used only resistance values as variables. All of the constraints expressed in terms of nodal (terminal) voltages and branch currents, which have to be obtained by explicitly solving an electrical network, become nonlinear. The feasible direction method [4] is employed to solve the nonlinear optimization problem. At each iteration step, extra effort is required to solve the electrical network for nodal voltages and branch currents, as well as their gradients by numerical differentiation.

Chowdhury [8] proposed a very interesting approach, where both the nodal voltages and the branch currents are selected as variables. The optimization problem is solved iteratively in two stages. In the first stage, all of the branch currents are fixed, and this leads to a convex programming problem solved by the conjugate gradient method [1]. In the second stage, all of the nodal voltages are assumed fixed with branch currents as variables, and this leads to a linear programming problem. In comparison with other methods, this method is more general and more efficient. Unfortunately, the conjugate gradient method is not efficient enough to solve large size P/G optimization problems arising in today's VLSI design.

A method proposed by Mitsuhashi and Kuh [11] further extends P/G network optimization to include P/G network topology selection. In this paper, we assume that the topology is fixed.

### III. PROBLEM FORMULATION AND GENERAL OPTIMIZATION PROCEDURE

Our work follows the formulation and the general optimization procedure of Chowdhury [8]. His results are first reviewed briefly in this section.

#### A. Problem Formulation

Let  $G = \{N, B\}$  be a P/G network with  $n$  nodes  $N = \{1, \dots, n\}$  and  $b$  branches  $B = \{1, \dots, b\}$ . Each branch  $i$  in  $B$  connects two nodes  $i1$  and  $i2$  with nodal voltages  $V_{i1}$  and  $V_{i2}$  such that current  $I_i$  flows from  $i1$  to  $i2$ . Let  $l_i$  and  $w_i$  be the length and width of branch  $i$ . Let  $\rho$  be the sheet resistivity. Then resistance  $r_i$  of branch  $i$  can be expressed as:  $r_i = (V_{i1} - V_{i2})/I_i = \rho(l_i/w_i)$ . The total P/G routing area, which is the objective function to be minimized, can be expressed as

$$f(\mathbf{V}, \mathbf{I}) = \sum_{i \in B} l_i w_i = \sum_{i \in B} \frac{\rho I_i l_i^2}{V_{i1} - V_{i2}}. \quad (1)$$

Instead of using widths  $w_i$ ,  $i \in B$  as variables, we choose to solve for branch current  $I_i$  and nodal voltages  $V_{i1}$  and  $V_{i2}$ . The constraints to be satisfied are as follows.

#### 1) The IR drop constraints.

$$\begin{aligned} V_j &\geq V_{j,\min} \text{ if node } j \text{ is connected to a power pad} \\ V_j &\leq V_{j,\max} \text{ if node } j \text{ is connected to a ground pad} \end{aligned} \quad (2)$$

where  $V_{j,\min}$  and  $V_{j,\max}$ ,  $j = 1 \dots n$  are given constants.

#### 2) The minimum width constraints.

$$w_i = \rho \frac{l_i I_i}{V_{i1} - V_{i2}} \geq w_{i,\min} \quad (3)$$

where  $w_{i,\min}$ ,  $i = 1 \dots b$  are given constants.

#### 3) The current density constraints (electromigration).

For a fixed thickness  $\sigma$  of a layer, this constraint for branch  $i$  can be expressed as [3]  $|I_i| \leq w_i \sigma$ . It can be rewritten as the following nodal voltage constraint:

$$|V_{i1} - V_{i2}| \leq \rho l_i \sigma. \quad (4)$$

#### 4) Equal width constraints.

The constraint can be written as  $w_i = w_j$  for segments  $i$  and  $j$ . In terms of nodal voltages and branch currents, we have

$$\frac{V_{i1} - V_{i2}}{l_i I_i} = \frac{V_{j1} - V_{j2}}{l_j I_j}. \quad (5)$$

#### 5) Kirchhoff's current law (KCL).

$$\sum_{i \in B(j)} s_i I_i = 0 \quad (6)$$

for each node  $j = \{1, \dots, n\}$  and  $B(j)$  is the set of indexes of branches connected to node  $j$  and  $s_i$  is 1, if the current direction for branch  $i$  is toward node  $j$  and  $-1$ , otherwise.

P/G network optimization is to minimize (1) subject to constraints (2)–(6). It will be referred to as problem **P**. Problem **P** is a constrained nonlinear optimization problem.

#### B. Relaxed Two-Step Optimization Procedure

To reduce the complexity of solving problem **P**, Chowdhury proposed the following relaxed two-step optimization procedure.

- Problem **P1**: Assuming that all branch currents are fixed, the objective function becomes

$$f(\mathbf{V}) = \sum_{i \in B} \frac{\alpha_i}{V_{i1} - V_{i2}} \quad (7)$$

where  $\alpha_i = \rho I_i l_i^2$ , subject to constraints (2), (4), and (5)<sup>1</sup> and the following constraint:

$$\frac{V_{i1} - V_{i2}}{I_i} \geq 0. \quad (8)$$

The constraint ensures that the current direction will not change during the optimization process.

- Problem **P2**: Assuming that all nodal voltages are fixed, the objective function becomes

$$f(\mathbf{I}) = \sum_{i \in B} \beta_i I_i \quad (9)$$

where  $\beta_i = (\rho l_i^2 / V_{i1} - V_{i2})$ , subject to (3), (5), (6), and the following fixed-current direction constraint:

$$\frac{I_i}{V_{i1} - V_{i2}} \geq 0. \quad (10)$$

Chowdhury showed that problem **P1** can be converted to an unconstrained convex programming problem and solved by the conjugate gradient method. **P2** is a linear programming problem. Therefore, solving **P** is to start with an initial feasible solution, then iteratively solve **P1**, then **P2**.

### IV. NEW LINEAR-PROGRAMMING-BASED ALGORITHM

The new method uses a sequence of linear programmings to solve the nonlinear programming problem **P1**. In this section, we present the method and prove that it always converges to the optimum solution of problem **P1**.

The basic idea is to linearize nonlinear objective function (7). To see this, we define the branch voltage drop variable as  $v_i = \text{sign}(I_i)(V_{i1} - V_{i2})$  for each branch  $i$ , where  $\text{sign}(x) = 1$  if  $x > 0$  and  $\text{sign}(x) = -1$  if  $x < 0$ . Note that  $v_i \geq 0$ . Then, in terms of  $v_i$ ,  $i = 1, \dots, b$ , the objective function (7) can be expressed as

$$f(\mathbf{v}) = \sum_{i \in B} \frac{|\alpha_i|}{v_i} \quad (11)$$

where  $\mathbf{v} = \{v_1, v_2, \dots, v_b\}^T$ . Suppose that we have an initial feasible solution  $\mathbf{v}^0$  and corresponding  $\mathbf{v}^0$  satisfying all the constraints. We then take the Taylor expansion of  $f(\mathbf{v})$  around  $\mathbf{v}^0$  and keep only the constant and linear terms. The resulting objective function is called  $g(\mathbf{v})$

$$g(\mathbf{v}) = f(\mathbf{v}^0) + \frac{\partial f(\mathbf{v}^0)}{\partial \mathbf{v}} (\mathbf{v} - \mathbf{v}^0) = \sum_{i \in B} \frac{2|\alpha_i|}{v_i^0} - \sum_{i \in B} \frac{|\alpha_i|}{v_i^0{}^2} v_i. \quad (12)$$

<sup>1</sup>Constraint (4) was not considered in [8].

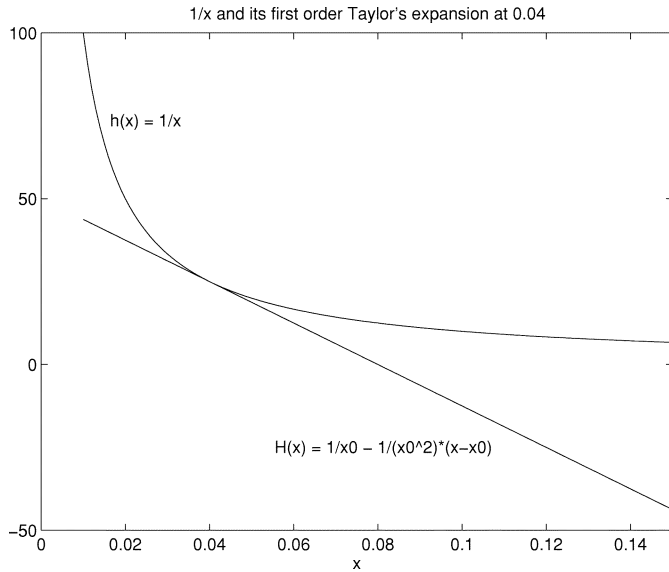

Fig. 1.  $h(x) = 1/x$  and its first-order expansion at 0.04.

Instead of minimizing  $f(\mathbf{v})$ , we minimize  $g(\mathbf{v})$  as long as these two functions satisfy the following property:

$$g(X) > g(Y) \implies f(X) > f(Y) \tag{13}$$

where  $\implies$  means *imply*. This requirement essentially says that as long as we reduce  $g(X)$ , we can always reduce  $f(X)$ .

To motivate our method, we first consider each individual term in the objective function (11), which has the following form  $h(x) = c/x$ ,  $x > 0$ , where  $c$  is a constant and  $c > 0$ . Fig. 1 draws function  $h(x) = c/x$ , with  $c = 1$ , and its linearized first-order Taylor expansion function  $H(x)$  at expansion point  $x_0 = 0.04$ . We note that both  $h(x)$  and  $H(x)$  are monotonically decreasing functions in  $x$  in the range  $(0, \infty)$  with the property that  $h(x) > H(x)$ .

Considering  $f(\mathbf{v})$  and  $g(\mathbf{v})$ , we have the following two optimization scenarios.

- 1) If all of the branch voltage drops  $v_i$  increase after optimization, we have  $f(\mathbf{v}^0) > f(\mathbf{v})$  and  $g(\mathbf{v}^0) > g(\mathbf{v})$ . Because all the terms in both  $f(\mathbf{v}^0)$  and  $g(\mathbf{v}^0)$  monotonically decrease as each  $v_i$  increases, property (13) is always satisfied.
- 2) If only some of the branch voltage drops increase and others decrease or stay unchanged, then property (13) may not be satisfied due to the fact that for  $x < x_0$ ,  $h(x)$  will increase very quickly, while  $H(x)$  only increases linearly. As a result, we may end up with  $f(\mathbf{v}) > f(\mathbf{v}^0)$ , while  $g(\mathbf{v}) < g(\mathbf{v}^0)$ .

In this case, we can limit the solution space to the neighborhood of  $\mathbf{v}^0$  such that property (13) holds by imposing the following constraint for each branch  $i$ :

$$\xi \cdot v_i^0 \leq v_i \leq (2 - \xi) \cdot v_i^0 \tag{14}$$

where  $\xi$  is called the *restriction factor*  $0 < \xi < 1$ . As will be shown in Theorem 1, we can always satisfy property (13) by choosing  $\mathbf{v}$  to be sufficiently close to  $\mathbf{v}^0$  ( $\xi$  is close enough to 1) as  $g(\mathbf{v})$  is essentially the first-order approximation of  $f(\mathbf{v})$ .

On the other hand, an increase in any branch voltage drop  $v_i$ ,  $i \in \{1, \dots, b\}$  always decreases  $f(\mathbf{v})$  and  $g(\mathbf{v})$ , according to scenario 1. This implies that the upper bound in (14) is redundant, and we can combine the solution space, where relation (13) holds in both scenarios, into a single space

$$\xi \cdot v_i^0 \leq v_i. \tag{15}$$

Fig. 2. Illustration of sequence of linear programmings.

In terms of nodal voltages, the linearized objective function and the restriction constraint can be rewritten as

$$g(\mathbf{V}) = \sum_{i \in B} \frac{2\alpha_i}{(V_{i1}^0 - V_{i2}^0)} - \sum_{i \in B} \frac{\alpha_i}{(V_{i1}^0 - V_{i2}^0)^2} (V_{i1} - V_{i2}) \tag{16}$$

$$\xi \cdot \text{sign}(I_i) (V_{i1}^0 - V_{i2}^0) \leq \text{sign}(I_i) (V_{i1} - V_{i2}). \tag{17}$$

Note that constraint (17) does not necessarily require that nodal voltage  $V_{ix}$ ,  $i \in \{1, \dots, n\}$  be close to their initial values. Because constraint (17) already implies constraint (8), we have the following optimization problem, denoted as **P3**: minimize (16)

$$g(\mathbf{V}) = \sum_{i \in B} \frac{2\alpha_i}{(V_{i1}^0 - V_{i2}^0)} - \sum_{i \in B} \frac{\alpha_i}{(V_{i1}^0 - V_{i2}^0)^2} (V_{i1} - V_{i2})$$

subject to

- (2):  $V_j \geq V_{j,\min}$  if node  $j$  is connected to a power pad,  $V_j \leq V_{j,\max}$ , if node  $j$  is connected to a ground pad;
- (3):  $(V_{i1} - V_{i2}) / (I_i) < (\rho l_i) / (w_i \min)$ ;
- (4):  $|V_{i1} - V_{i2}| \leq \rho l_i \sigma$ ;
- (5):  $(V_{i1} - V_{i2}) / (l_i I_i) = (V_{j1} - V_{j2}) / (l_j I_j)$ ;
- (17):  $\xi \cdot \text{sign}(I_i) (V_{i1}^0 - V_{i2}^0) \leq \text{sign}(I_i) (V_{i1} - V_{i2})$ .

Problem **P3** is a linear programming problem. For convenience, we use  $\Gamma$  to denote the feasible region of problem **P3** defined by (2)–(5) and (17). We use  $\Omega$  to denote the feasible region of problem **P1** as defined by constraints (2)–(5) and (8). Clearly,  $\Gamma \subseteq \Omega$ .

The procedure for solving problem **P1** can be transformed to the problem of repeatedly choosing  $\xi$  and solving **P3** until the optimum solution is found. This sequence of the linear programming process is illustrated in Fig. 2 in terms of solution space of problem **P1** and solution spaces of problem **P3** ( $\Gamma_0$  to  $\Gamma_n$ ).  $X_{\min}$  is the global minimum of convex problem **P1**. It shows how the new method approaches the global minimum by several linear programming processes iteratively.

The entire optimization procedure is summarized as follows:

#### New P/G Network Optimization Algorithm

- 1) Analyze network  $G$  to obtain initial  $\mathbf{V}^k$ ,  $\mathbf{I}^k$  for  $k = 0$ .
- 2) Construct the minimum width constraints (3), current density constraints (4), equal width constraints (5), additional constraints (17) using  $\mathbf{I}^k$ .
- 3) Minimize  $g(\mathbf{V}^k)$  subject to constraints (2), (4), (3), (5), and (17) by a sequence of linear programmings, record the result as  $\mathbf{V}_l^k$ ,  $l$  begins from 1. If

TABLE I  
COMPARISON OF THE NEW ALGORITHM AGAINST THE CONJUGATE GRADIENT METHOD

P/G network	#node	#bch	new algorithm			conjugate gradient			speedup

$f(\mathbf{V}_l^k) > f(\mathbf{V}_{l-1}^k)$ , perform line search along the direction  $\mathbf{d} = (\mathbf{V}_{l-1}^k - f(\mathbf{V}_l^k))$  until  $f(\mathbf{V}_l^k) \leq f(\mathbf{V}_{l-1}^k)$ . Record the result from the last iteration  $l$  as  $\mathbf{V}^{k+1}$ .

- 4) Construct the minimum width and its companion constraint (3), (5), and (10) using  $\mathbf{V}^{k+1}$  for each branch.
- 5) Minimize objective function (9) subject to the constraints (3), (5), (6), and (10) by linear programming and record the result as  $\mathbf{I}^{k+1}$ .
- 6) If  $|f(\mathbf{V}^{k+1}, \mathbf{I}^{k+1}) - f(\mathbf{V}^k, \mathbf{I}^k)| < \epsilon$ ,  $\epsilon$  is the termination criterion, then stop, otherwise, set  $k = k + 1$  and goto step 2.

For the new P/G optimization algorithm, we have the following theoretical result.

*Theorem 1:* There exists a  $\xi$  so that step 3 always converges to the global minimum in  $\Omega$ . The proof of this theorem can be found in the Appendix.

Although we show theoretically that given  $g(\mathbf{V}_l^k) < g(\mathbf{V}_{l-1}^k)$ , we can always find a  $\xi$  in step 3 such that  $f(\mathbf{V}_l^k) < f(\mathbf{V}_{l-1}^k)$ . However, in practice, it is not very efficient to find such a  $\xi$  by repeatedly decreasing  $\xi$  and solving **P3** in case of  $f(\mathbf{V}_l^k) \geq f(\mathbf{V}_{l-1}^k)$ . In our implementation, we perform a one-dimensional line search to find the solution point.

Specifically, given  $\mathbf{V}_l^k$  and  $\mathbf{V}_{l-1}^k$ , we define the search direction as  $\mathbf{d}_l^k = \mathbf{V}_l^k - \mathbf{V}_{l-1}^k$ . Line search finds an  $\alpha \in [0, 1]$  such that

$$f(\alpha \mathbf{d}_l^k + \mathbf{V}_{l-1}^k) < f(\mathbf{V}_{l-1}^k) \quad (18)$$

$\alpha \mathbf{d}_l^k + \mathbf{V}_{l-1}^k$  becomes new  $\mathbf{V}_l^k$  for the next iteration. This can be accomplished by any line-search algorithm. In our implementation, the golden section method [10] is used.

We note that a similar technique, called *successive linear programming* [1], was first proposed by Griffith and Stewart to solve problems in oil and chemical industries [10]. A similar idea was also used by M. Sarrafzadeh *et al.*, to compute the best delay budget constraints for timing-driven placement [13].

## V. PRACTICAL CONSIDERATIONS AND IMPLEMENTATION ISSUES

In this section, we describe some practical considerations on how to apply the proposed method to optimize P/G networks in practice.

- **Algorithm scalability.** In practice, the number of linear programs needed to reach the optimum solution is only a few. Thus, the time complexity of our method is proportional to that of linear programming. It is known that linear programs can be solved in polynomial time using the interior point method [1]. This makes our method very promising for optimizing very large P/G networks.
- **Input data scaling.** For practical P/G networks, the module currents are usually in the range of  $1 \times 10^{-9}$  A. Branch currents and

branch voltages could become very small without using scaling. This would cause some numerical problems for linear program solvers. In our implementation, scaling is used.

- **Converting power networks to ground networks.** Power networks should be transferred into ground networks to further improve the numerical stability. This is due to the fact that voltage drops close to zero can be represented more precisely than the voltage drops close to any other values. For example, the voltage drop of  $2.5 \times 10^{-5}$  has to be represented by 4.999 975 if the source voltage is 5 V. If we apply data scaling by multiplying  $10^5$  to all the voltage drops,  $2.5 \times 10^{-5}$  become 2.5 which are more linear-solver friendly than 4 999 975, as 499 975 can easily lead to ill-conditions or round errors in solving linear equations. It can be shown that a power network can be transferred into a ground network by using the following transformation rules: 1) short-circuit all the VDD pads to the ground and 2) inverse the directions of all the independent current sources.
- **Zero branch voltages.** The branch voltage  $v_i$  in objective function (11) can be zero or takes a very small numerical value. In this case, we just simply ignore the branch (and its incident nodal voltages and branch currents) in the objective function and all the constraints. The corresponding branch will take the minimum width after the optimization.

## VI. EXPERIMENTAL RESULTS

A CAD tool for P/G network optimization has been developed based on the proposed sequence-of-linear-programming method. For comparison, Chowdhury's conjugate gradient method [8] has also been carefully implemented.<sup>2</sup> A set of P/G networks with ten to more than ten thousand segments has been tested. All experiments are performed on a Sun workstation with 296-MHz clock rate.

Table I compares the result of the new algorithm with that of the conjugate gradient method. No equal width constraints are considered here since Chowdhury's conjugate gradient method cannot handle these constraints well. In Table I, columns 1 to 3 list, respectively, the P/G network name, the number of nodes in the P/G network (*#node*), and the number of branches (*#bch*). Notice that the name *pg100 × 100* means that the circuit consists of 100 rows and 100 columns P/G strips. So, the sizes of the circuits in terms of nodes are approximately equal to *# of rows × # of columns* as shown in column 2. The number of iterations (*#iter*) (solving **P1-P2**), CPU time in seconds (*CPU*), and the reduced chip area of the original area in percentage [*area reduced (%)*] are reported in columns 4–6 for the new algorithm and columns 7–9 for the conjugate gradient method. For example, for P/G network *pg20 × 20*, the new method reduces the chip area used by 90.6%, while the conjugate gradient method reduces the chip area used by 85.3%. Note that the area improvement strongly depends on the original layouts.

We have the following observations.

<sup>2</sup>In fact, our research was motivated by our initial attempt in applying the conjugate gradient method for P/G network optimization in an industry setting.

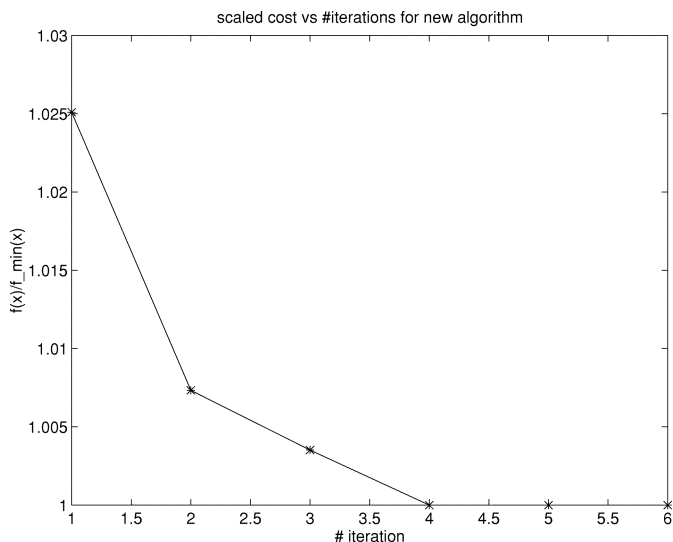

Fig. 3. Cost reduction with the number of iterations.

- For large P/G networks  $pg3 \times 500$ ,  $pg300 \times 10$ , and  $pg100 \times 100$ , the conjugate gradient method finds solutions that use chip areas much more than that of the new method.
- The new algorithm is orders of magnitude faster than the conjugate gradient method.
- We have observed that for all of the P/G networks tested, with one iteration, the new algorithm is able to reduce most of the chip area that can be reduced, i.e., finds a solution that is very close to the optimum. Fig. 3 shows how the objective function decreases with the number of iterations for an example network.

#### Analysis:

- Theoretically, both the conjugate gradient and the sequence-of-linear-programming methods should converge to an optimal solution. However, in practice, due to the numerical problem inherent in the conjugate gradient method, the conjugate directions may deteriorate during the process of optimization such that the algorithm gets stuck at a solution far away from the optimum. In our implementation, we reinitialize the direction vector if no improvement can be made along the present direction. This process is repeated until the reinitialized direction cannot further reduce the cost function.
- The way the penalty function is constructed also affects the solution quality of the conjugate gradient method. After solving problem **P2** for branch currents by linear programming, some widths of the P/G segment may be reduced to a minimum value. Those segments will lead to the infinite penalty cost and the infinite conjugate direction vector. The whole process will stall after only one **P1-P2** iteration. Therefore, it is hard for the conjugate gradient method to find the optimal solution. As a remedy, in our implementation, we slightly increase the required minimum width value when solving **P2**.
- In the experiments above, the restriction factor  $\xi$  is set to 0.85. Recall that the feasible region  $\Gamma$  for linear program **P3** is controlled by  $\xi$ . The closer  $\xi$  to 1, the smaller the region  $\Gamma$ , and the better  $g(\mathbf{V})$  approximates  $f(\mathbf{V})$ . This implies that the total number of linear programming iterations (solving **P1-P3**) will increase, but the chance to find the minimum solution of the original problem increases. On the other hand, if we reduce  $\xi$  closer to 0, the feasible region  $\Gamma$  of problem **P3** enlarges. Then, the linearized function  $g(\mathbf{V})$  may not be able to approximate the original function  $f(\mathbf{V})$  well. As a result, the sequence of linear programmings may converge to a solution with the cost higher than the optimum one.

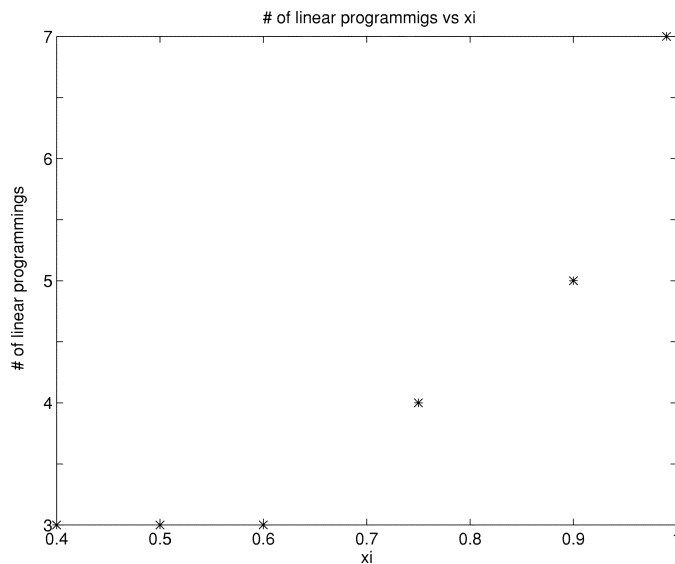

Fig. 4. Number of linear programs versus  $\xi(x_i)$ .

Fig. 5. Final cost versus  $\xi(x_i)$ .

This observation has been confirmed by the experiment on the example network  $pg4 \times 4$  without using line search in step 3 as shown in Figs. 4 and 5.

In addition to  $\Gamma$ , the number of linear programs in **P3** also depends on the initial solutions as shown in Fig. 1. But for the given P/G networks, we find that it takes a few (less than 10) linear programs to reach a solution for all the cases. Therefore, the new algorithm converges very quickly.

Table II describes the results of applying the new algorithm to the same set of P/G networks but with practical equal-width constraints. Here, we require widths of all the wire segments along the same chain to be equal. The number of such constraints, #eq-consts, is listed in the second column for each network. Not surprisingly, we can see from the table that the area reduced may not be as much as we can achieve without equal-width constraints. In comparison to the instances without equal-width constraints, the CPU time used can be more ( $pg100 \times 100$ ) or less ( $pg300 \times 10$ ). The reason for using less CPU time (as in the case of  $pg300 \times 10$ ) is due to the reduction of number of iterations in solving **P3**, since a reduced search space is considered. The reason for more

TABLE II  
EXPERIMENTAL RESULTS OF RUNNING THE NEW ALGORITHM  
WITH EQUAL WIDTH CONSTRAINTS

P/G network	#eq-consts	#iter	CPU	percentage of area reduced
pg4x4	12	2	0.3	50.0
pg20x20	56	2	5.2	90.3
pg3x500	503	2	366.9	51.1
pg300x10	200	2	198.4	93.7
pg100x100	397	2	5154.2	80.6

CPU time (as in the case of  $pg100 \times 100$ ) is due to more constraints in each linear program and more CPU time for each iteration.

## VII. CONCLUSION AND FUTURE WORK

A sequence-of-linear-programming-based method has been proposed and implemented for determining the widths of wire segments in a P/G network so that the chip area required by the P/G network is minimized, while ensuring  $IR$  voltage drops and electromigration constraints. We have shown theoretically that the new method is capable of finding the solution as good as that by the best known method based on conjugate gradient scheme. Experimental results have demonstrated that the proposed method is orders of magnitude faster than the best known method with constantly *better* quality solutions.

In this work, we model P/G networks as resistor-only networks. We notice that capacitive and inductive induced transient voltage fluctuations are major concerns for P/G networks in current and future technologies. However, we view our P/G optimization technique as one essential step toward designing robust power delivery networks. It was shown in [2] that transient voltage noise on some P/G segments can be efficiently suppressed by adding decoupling capacitors (decaps) around those P/G wires. Such a decap allocation scheme will make the resulting P/G grids more like resistive networks as decaps serve as low-pass filters. The  $IR$  drops due to the dc components of the voltages on the P/G networks and electromigration related current density problems have to be addressed by wire sizing or topology changes. Further work will be extended toward P/G network optimization with capacitive and inductive parasitics driven by time-varying current sources.

## APPENDIX

Let  $f(\mathbf{x})$  be the objective function of problem **P1** and  $g(\mathbf{x})$  be the linearized version of  $f(\mathbf{x})$ . Consider an initial starting point  $\mathbf{x}_0$  and a solution point  $\mathbf{x}$  found by solving LP problem **P3**.

Let  $\Gamma$  denote the feasible region of problem **P3** defined by (2)–(4) and (17). Since  $\Gamma$  is a function of restriction factor  $\xi$  defined in (17), we also rewrite it as  $\Gamma(\xi)$ .

We begin our proof by first proving the following lemma.

*Lemma 1:* For each  $\mathbf{x}_0$ , there exists a  $\xi$  and a nonempty vicinity  $\Gamma(\xi)$  of  $\mathbf{x}_0$  such that if  $g(\mathbf{x}) < g(\mathbf{x}_0)$ ,  $\mathbf{x} \in \Gamma(\xi)$ , then  $f(\mathbf{x}) < f(\mathbf{x}_0)$ .

*Proof:* Let  $\mathbf{d} = \mathbf{x} - \mathbf{x}_0$  be the moving direction. According to the Taylor expansion, we have

$$f(\mathbf{x}_0 + \alpha \mathbf{d}) = f(\mathbf{x}_0) + \alpha \nabla f(\mathbf{x}_0) \mathbf{d} + o(\alpha) \quad (19)$$

where  $o(\alpha)$  is a lower order infinity than  $\alpha$ , i.e.

$$\lim_{\alpha \rightarrow 0} \frac{o(\alpha)}{\alpha} = 0.$$

Notice that  $g(\mathbf{x}) = g(\mathbf{x}_0) + \nabla f(\mathbf{x}_0)(\mathbf{x} - \mathbf{x}_0)$  and  $g(\mathbf{x}) < g(\mathbf{x}_0)$  as given by Lemma 1, so

$$g(\mathbf{x}_0) - g(\mathbf{x}) = -\nabla f(\mathbf{x}_0)(\mathbf{x} - \mathbf{x}_0) > 0 \quad (20)$$

$$\nabla f(\mathbf{x}_0)(\mathbf{x} - \mathbf{x}_0) = \nabla f(\mathbf{x}_0) \mathbf{d} < 0. \quad (21)$$

Rewriting (19), we have

$$f(\mathbf{x}_0 + \alpha \mathbf{d}) = f(\mathbf{x}_0) + \alpha \left( \nabla f(\mathbf{x}_0) \mathbf{d} + \frac{o(\alpha)}{\alpha} \right). \quad (22)$$

It is easy to see that we can always select a small enough  $\alpha$  such that

$$\nabla f(\mathbf{x}_0) \mathbf{d} + \frac{o(\alpha)}{\alpha} < 0. \quad (23)$$

Hence,

$$f(\mathbf{x}_0 + \alpha \mathbf{d}) < f(\mathbf{x}_0). \quad (24)$$

As we can make  $\xi$  as close to one as possible, thus,  $|\mathbf{d}|$  as small as possible, we can always obtain a  $\xi$  so that  $\alpha$  can be 1, i.e.,  $f(\mathbf{x}_0 + \mathbf{d}) < f(\mathbf{x}_0)$ . If  $\xi = 1$ , there still exists a nonzero  $\mathbf{d}$  such that  $g(\mathbf{x}_0 + \mathbf{d}) < g(\mathbf{x}_0)$ . Therefore, it must follow that  $f(\mathbf{x}_0 + \mathbf{d}) < f(\mathbf{x}_0)$  as both  $f(\mathbf{x})$  and  $g(\mathbf{x})$  are monotonically decreasing functions in  $\mathbf{x}$ . Lemma 1 is proved.

Now, we are ready to prove Theorem 1.

*Theorem 1:* There exists a  $\xi$  so that step 3 always converges to the global minimum in  $\Omega$ .

*Proof:* For function  $f(\mathbf{x}) = \sum_{i=1}^n (1/x_i)$ , the truncated linear Taylor expansion around  $\mathbf{x}_0$  is  $g(\mathbf{x}) = \sum_{i=1}^n ((1/x_{0i}) - (x_i - x_{0i})/(x_{0i}^2))$ . According to Lemma 1, given an initial point  $\mathbf{x}_0 = \mathbf{V}_1^k$ , one can always find a nonempty vicinity of  $\mathbf{x}_0$ , by increasing  $\xi$  close enough to 1, such that minimizing the linear expansion  $g$  at  $\mathbf{V}_{i+1}^k$  also decreases the original function  $f$ .

Hence, a decreasing sequence  $\{f(\mathbf{V}_1^k), f(\mathbf{V}_2^k), \dots, f(\mathbf{V}_l^k)\}$  is generated and guarantees to converge to a local minimum. Since  $f(X)$  is a convex function, the local minimum is also the global minimum, therefore, step 3 in the new algorithm will converge to the global minimum in  $\Omega$ .

## ACKNOWLEDGMENT

The authors wish to thank Dr. L.-P. Yuan and Dr. D. Lungeanu, Synopsys Corporation, and Prof. E. Kuh, University of California, Berkeley, for several helpful discussions on P/G network design.

### Comments on "Handling Soft Modules in General Nonslicing Floorplan Using Lagrangian Relaxation"

Teng-Sheng Moh and Tsu-Shuan Chang

The most important contribution in the above paper by Young *et al.* [1] is that they devised an efficient method to compute the shapes of soft modules to give the optimal packing, as described by the authors. We would like to clarify a misunderstanding that occurred when the authors referred to our paper [2] and stated, "However, all these methods are limited to placement topology of rectangular dissection only, i.e., slicing."<sup>1</sup> The problem formulation in [2] uses the geometric figure and, thus, can deal with both sliced and nonsliced floorplans. To our best knowledge, using geometric programming to find a global optimal size for modules in very large scale integration (VLSI) floorplanning was first proposed in [3]. Since the primal problem of their paper falls into the same mathematical format as that in [3], Young *et al.* should have used [3] as a reference in their paper. We would like to take this opportunity to explain how the geometric figure can be used for nonsliced floorplans, and the relationship among several relevant papers.

Regarding the use of geometric figures for nonsliced floorplans, the layout in Fig. 1 is used as an example, which is listed as Fig. 1b in the paper by Young *et al.* [1]. For sake of consistency, the procedure quoted in [2] will be briefly presented. A geometric figure  $GF[S, W]$  is an abstract representation of a partition in the  $(X, Y)$ -plane, where  $S$  is a set of squares representing the cells, and  $W$  is a set of straight lines representing the adjacency between cells. In the geometric figure, the enclosure boundary  $bnd$  is represented by four small circles representing the four sides of  $bnd$ . These four sides are labeled  $bnd^B$ ,  $bnd^T$ ,  $bnd^R$ , and  $bnd^L$  which are placed counterintuitively at the top, bottom, left, and right sides of the geometric figure. For each  $s \in S$ , let  $s^L$ ,  $s^R$ ,  $s^T$ , and  $s^B$  represent the left, right, top, and bottom sides of  $s$ . For every  $s$  and  $t \in S$ ,  $(s^T, t^B) \in W$  is a straight line from the top side of square  $s$  to the bottom side of square  $t$ . Similarly,  $(s^R, t^L)$  is a straight line from the right side of square  $s$  to the left side of square  $t$ . Furthermore, a straight line  $(s^T, bnd^B)$  is added to  $W$  from the top

Fig. 1. Given partition.

of each square  $s$  which lies on the top end of the geometric figure to  $bnd^B$ . Similarly,  $(s^R, bnd^L)$ ,  $(bnd^T, s^B)$ , and  $(bnd^R, s^L)$  are added to  $W$  for each square  $s$  lying on the right, bottom, and left end of the geometric figure. Clearly, straight lines in  $W$  are either in forms of  $(s^T, t^B)$ , called vertical straight line, or  $(s^R, t^L)$ , called horizontal straight line, for some  $s$  and  $t$  in either  $S$  or  $bnd$ .

By following the procedure, we can obtain the corresponding geometric figure shown in Fig. 2 from the partition of Fig. 1. Comparing Fig. 2 with the original partition in Fig. 1, we can see that the geometric figure is applicable to both sliced and nonsliced floorplans. Although our previous paper [2] stated in the first sentence of the Conclusion "A general nonsliced floorplanning problem has been discussed in this paper," the numerical examples used are all sliced floorplans. We probably should at least present one nonsliced floorplan such as this one among our examples to avoid any confusion.

Once the geometric figure of the partition is obtained, we can assign  $X$  and  $Y$  variables according to the procedure described in [2]. Intuitively, all of the horizontal straight lines are assigned as the same variable if they are linked together, such as  $x_2$ . Once  $X$  and  $Y$  variables are given, we can get  $X$ - and  $Y$ -graphs, which are used to derive inequality constraints to preserve partition. The corresponding  $X$ - and  $Y$ -graphs are given in Fig. 3. The  $X$ -graph is obtained from left to right. Intuitively, an arrow is at least added from  $x_i$  to  $x_j$ , if there is a cell between  $x_i$  and  $x_j$ . Thus, the arrow from  $x_i$  to  $x_j$  means that we have the adjacency inequality constraint  $x_i \leq x_j$ , such as from Fig. 3

$$x_3 \leq x_2 \quad \text{and} \quad y_1 \leq y_2. \quad (1)$$

Note that there are redundant inequalities from the  $X$ - and  $Y$ -graphs. Thus, the number of such constraints can be reduced.

Let us now clarify the contribution of some relevant papers. The problem dealt in [2] is derived from that in [4]. When there is no aspect ratio, the approach in [4] can produce an optimal solution with zero wasted areas, although sometimes the solution does not exactly match the given partition that is mentioned in [2]. The approach in [4] cannot deal with a problem with aspect ratio. In [2], a global optimal solution was found by using geometric programming, which preserves the partition and satisfies the aspect ratio for each cell.

As mentioned, using geometric programming to find a global optimal size for modules in VLSI floorplanning was first published in [3]. However, that original problem formulation was not designed to preserve a given partition, and the aspect ratio was not taken into account explicitly. To deal with such a problem in [2], the original problem was successfully reformulated in a higher dimension and solved to obtain
